

## Phys 512 Problem Set 1

Due on github Friday Sep 17 at 11:59 PM. Please place all materials in a subdirectory `problem_sets/ps1` off of your main course repository so the TAs can find things more easily. You may discuss problems, but everyone must write their own code.

**Problem 1:** We saw in class how Taylor series/roundoff errors fight against each other when deciding how big a step size to use when calculating numerical derivatives. If we allow ourselves to evaluate our function  $f$  at four points ( $x \pm \delta$  and  $x \pm 2\delta$ ),

a) what should our estimate of the first derivative at  $x$  be? Rather than doing a complicated fit, I suggest thinking about how to combine the derivative from  $x \pm \delta$  with the derivative from  $x \pm 2\delta$  to cancel the next term in the Taylor series.

b) Now that you have your operator for the derivative, what should  $\delta$  be in terms of the machine precision and various properties of the function? Show for  $f(x) = \exp(x)$  and  $f(x) = \exp(0.01x)$  that your estimate of the optimal  $\delta$  is at least roughly correct.

**Problem 2:** Write a numerical differentiator with prototype:

```
def ndiff(fun,x,full=False):
```

where `fun` is a function and `x` is a value. If `full` is set to `False`, `ndiff` should return the numerical derivative at `x`. If `full` is `True`, it should return the derivative, `dx`, and an estimate of the error on the derivative. I suggest you use the centered derivative

$$f' \approx \frac{f(x + dx) - f(x - dx)}{2dx}$$

Your routine should estimate the optimal `dx` then use that in calculating the derivative. If you're feeling ambitious, write your code so that `x` can be an array, not just a single number. If you do that, you may actually wish to save your code as you might use it in the future.

**Problem 3:** Lakeshore 670 diodes (successors to the venerable Lakeshore 470) are temperature-sensitive diodes used for a range of cryogenic temperature measurements. They are fed with a constant  $10 \mu\text{A}$  current, and the voltage is read out. Lakeshore provides a chart that converts voltage to temperature, available [here](#), or you can look at the text file I've helpfully copied and pasted (`lakeshore.txt`). The first column is the temperature, the second column is the corresponding voltage. If you choose to use it (you don't need to), the third column is  $dV/dT$  at that temperature. Write a routine that will take an arbitrary voltage and interpolate to return a temperature.

You should also make some sort of quantitative (but possibly rough) estimate of the error in your interpolation as well (this is a common situation where you have been presented with data and have to figure out *some* idea of how to get error estimates).

Your prototype should be:

```
def lakeshore(V,data):
```

where data is the output of

```
dat=np.loadtxt('lakeshore.txt')
```

Your code should support V being either a number or an array, and it should return the interpolated temperature and your uncertainty on the temperature.

**Problem 4:** Take  $\cos(x)$  between  $-\pi/2$  and  $\pi/2$ . Compare the accuracy of polynomial, cubic spline, and rational function interpolation given some modest number of points, but for fairness each method should use the same points. Now try using a Lorentzian  $1/(1+x^2)$  between -1 and 1.

What should the error be for the Lorentzian from the rational function fit? Does what you got agree with your expectations when the order is higher (say  $n=4$ ,  $m=5$ )? What happens if you switch from `np.linalg.inv` to `np.linalg.pinv` (which tries to deal with singular matrices. For sufficiently small eigenvalues in matrix A, `pinv` sets them to be 0 in  $A^{-1}$ , while they would be something very large when using regular `inv`)? Can you understand what has happened by looking at  $p$  and  $q$ ? As a hint, think about why we had to fix the constant term in the denominator, and how that might generalize.
